MARL Learning Framework

MARL Learning Process

- The game model defines the learning environment
- Interaction data from joint policy π^z are collected as $\mathcal{D}^z = \{h^{te} \mid e = 1, \dots, z\}, z \geq 0$
- A learning algorithm updates the joint policy as $\pi^{z+1} = \mathbb{L}(\mathcal{D}^z, \pi^z)$
- The learning goal is a chosen solution concept, e.g. Nash equilibrium

Inputs of Policies Depend on Game Model

Partially observable stochastic games

Convergence

To evaluate the learning algorithm, we typically assess whether the learnt joint policy has **converged** to an optimal joint policy:

$$\lim_{z \rightarrow \infty} \pi^z = \pi^*$$

- Optimal joint policies may differ depending on the solution concept
- There may be many valid solutions \Rightarrow e.g. multiple Nash equilibria
- In practice, we cannot collect infinite data $z \rightarrow \infty$
 \Rightarrow Learning typically stops after a predefined 'budget' (e.g. training steps)

Single-Agent RL Reductions

The simplest way to apply RL algorithms in multi-agent settings is to reduce them to single-agent problems.

Single-Agent RL Reductions

The simplest way to apply RL algorithms in multi-agent settings is to reduce them to single-agent problems.

Central learning:

- Apply one single-agent RL algorithm to control all agents centrally
⇒ A central policy is learned over the joint action space

Single-Agent RL Reductions

The simplest way to apply RL algorithms in multi-agent settings is to reduce them to single-agent problems.

Central learning:

- Apply one single-agent RL algorithm to control all agents centrally
⇒ A central policy is learned over the joint action space

Independent learning:

- Apply single-agent RL algorithms to each agent independently
⇒ Agents do not explicitly consider or represent each other

Central Learning

Central Learning

Central learning: learn a single central policy π_c which receives observations of all agents and selects an action for each agent (i.e. joint action (a_1, \dots, a_n)).

- Requires transforming the joint reward (r_1, \dots, r_n) into a single scalar reward r

Central learning: learn a single central policy π_c which receives observations of all agents and selects an action for each agent (i.e. joint action (a_1, \dots, a_n)).

- Requires transforming the joint reward (r_1, \dots, r_n) into a single scalar reward r
- This can be easy in some settings, e.g. in games with common rewards $r = r_i$, but difficult in zero-sum or general-sum games

Central learning: learn a single central policy π_c which receives observations of all agents and selects an action for each agent (i.e. joint action (a_1, \dots, a_n)).

- Requires transforming the joint reward (r_1, \dots, r_n) into a single scalar reward r
- This can be easy in some settings, e.g. in games with common rewards $r = r_i$, but difficult in zero-sum or general-sum games
- May not scale well with the number of agents, as the joint action space may grow exponentially with the number of agents

Central learning: learn a single central policy π_c which receives observations of all agents and selects an action for each agent (i.e. joint action (a_1, \dots, a_n)).

- Requires transforming the joint reward (r_1, \dots, r_n) into a single scalar reward r
- This can be easy in some settings, e.g. in games with common rewards $r = r_i$, but difficult in zero-sum or general-sum games
- May not scale well with the number of agents, as the joint action space may grow exponentially with the number of agents
- May also not be suitable in environments that require agents to act independently based on local observations

Algorithm Central Q-learning

- 1: Initialize: $Q(s, a) = 0$ for all $s \in S$ and $a \in A = A_1 \times \dots \times A_n$
 - 2: Repeat for every episode:
 - 3: **for** $t = 0, 1, 2, \dots$ **do**
 - 4: Observe current state s^t
 - 5: With probability ϵ : choose random joint action $a^t \in A$
 - 6: Otherwise: choose joint action $a^t \in \arg \max_a Q(s^t, a)$
 - 7: Apply joint action a^t , observe rewards r_1^t, \dots, r_n^t and next state s^{t+1}
 - 8: Transform r_1^t, \dots, r_n^t into scalar reward r^t
 - 9: $Q(s^t, a^t) \leftarrow Q(s^t, a^t) + \alpha[r^t + \gamma \max_{a'} Q(s^{t+1}, a') - Q(s^t, a^t)]$
-

Independent Learning

Independent Learning

Independent learning: each agent i learns its policy π_i using only its local history of observations.

- From the perspective of each agent i , the environment transition function looks like this:

$$\mathcal{T}_i(s^{t+1}|s^t, a_i) \propto \sum_{a_{-i} \in A_{-i}} \mathcal{T}(s^{t+1}|s^t, \langle a_i, a_{-i} \rangle) \prod_{j \neq i} \pi_j(a_j|s^t)$$

- As each agent j 's policies are updated, the action probabilities π_j change
 \Rightarrow From agent i 's perspective, the transition function \mathcal{T}_i appears non-stationary!

Independent Q-learning

Algorithm Independent Q-learning (IQL) for stochastic games

- 1: *// Algorithm controls agent i*
 - 2: Initialize: $Q_i(s, a_i) = 0$ for all $s \in S, a_i \in A_i$
 - 3: Repeat for every episode:
 - 4: **for** $t = 0, 1, 2, \dots$ **do**
 - 5: Observe current state s^t
 - 6: With probability ϵ : choose random action $a_i^t \in A_i$
 - 7: Otherwise: choose action $a_i^t \in \arg \max_{a_i} Q_i(s^t, a_i)$
 - 8: (meanwhile, other agents $j \neq i$ choose their actions a_j^t)
 - 9: Observe own reward r_i^t and next state s^{t+1}
 - 10: $Q_i(s^t, a_i^t) \leftarrow Q_i(s^t, a_i^t) + \alpha[r_i^t + \gamma \max_{a'_i} Q_i(s^{t+1}, a'_i) - Q_i(s^t, a_i^t)]$
-

IQL and CQL in Level-Based Foraging

- IQL can learn more quickly, as CQL needs to explore $6^2 = 36$ actions in each state

Modes of Operation in MARL

Modes of Operation in MARL: **self-play** and **mixed-play**

Self-play:

- **Algorithm self-play:** all agents use the same learning algorithm (and parameters)
- **Policy self-play:** agent's policy is trained directly against itself

Mixed-play

- Agents use different learning algorithms

MARL Challenges

Singe-Agent RL Challenges

- Unknown environment dynamics
- Exploration-exploitation dilemma
- Non-stationarity from bootstrapping
- Temporal credit assignment

MARL Challenges

Singe-Agent RL Challenges

- Unknown environment dynamics
- Exploration-exploitation dilemma
- Non-stationarity from bootstrapping
- Temporal credit assignment

Multi-Agent RL Challenges

- Non-stationarity from multiple learning agents
- Equilibrium selection
- Multi-agent credit assignment
- Scaling tom many agents

Non-Stationarity

A stochastic process $X_{t \in \mathbb{N}^0}^t$ is stationary if:

- The probability distribution of $X^{t+\tau}$ does not depend on $\tau \in \mathbb{N}^0$, where t and $t + \tau$ are time indices
- This means that the dynamics of the process do not change over time

Non-Stationarity

A stochastic process $X^t_{t \in \mathbb{N}^0}$ is stationary if:

- The probability distribution of $X^{t+\tau}$ does not depend on $\tau \in \mathbb{N}^0$, where t and $t + \tau$ are time indices
- This means that the dynamics of the process do not change over time

Consider: X^t samples the state s^t at each time step t :

- In a MDP, X^t is completely defined by the state transition function $\mathcal{T}(s^t | s^{t-1}, a^{t-1})$ and the agent's policy π which selects an action $a \sim \pi(.|s)$

Non-Stationarity

A stochastic process $X_{t \in \mathbb{N}^0}^t$ is stationary if:

- The probability distribution of $X^{t+\tau}$ does not depend on $\tau \in \mathbb{N}^0$, where t and $t + \tau$ are time indices
- This means that the dynamics of the process do not change over time

Consider: X^t samples the state s^t at each time step t :

- In a MDP, X^t is completely defined by the state transition function $\mathcal{T}(s^t | s^{t-1}, a^{t-1})$ and the agent's policy π which selects an action $a \sim \pi(.|s)$
- If π does not change, then this process is stationary (i.e. independent of t) because s^t depends only on s^{t-1} , a^{t-1} and a^{t-1} depends only on s^{t-1} via $\pi(.|s^{t-1})$

Non-Stationarity

A stochastic process $X^t_{t \in \mathbb{N}^0}$ is stationary if:

- The probability distribution of $X^{t+\tau}$ does not depend on $\tau \in \mathbb{N}^0$, where t and $t + \tau$ are time indices
- This means that the dynamics of the process do not change over time

Consider: X^t samples the state s^t at each time step t :

- In a MDP, X^t is completely defined by the state transition function $\mathcal{T}(s^t | s^{t-1}, a^{t-1})$ and the agent's policy π which selects an action $a \sim \pi(\cdot | s)$
- If π does not change, then this process is stationary (i.e. independent of t) because s^t depends only on s^{t-1} , a^{t-1} and a^{t-1} depends only on s^{t-1} via $\pi(\cdot | s^{t-1})$
- However, in RL the policy does change over time through the learning $\pi^{z+1} = \mathbb{L}(\mathcal{D}^z, \pi^z)$, which leads to **non-stationarity** in X^t

Non-Stationarity in Multi-Agent Settings

In MARL, non-stationarity is exacerbated by multiple agents changing their policies!

- $\pi^{z+1} = \mathbb{L}(\mathcal{D}^z, \pi^z)$ updates an *entire* joint policy $\pi^z = (\pi_1^z, \dots, \pi_n^z)$
- Environment is non-stationary from each agent's perspective
- Can cause cyclic learning dynamics where agents co-adapt to each other's changing policies

Equilibrium Selection

Equilibrium selection: a game may have multiple equilibria, which can yield different expected returns to the agents.

- **Example:** Stag Hunt matrix game
- Two hunters choose: cooperate to hunt stag (S) or go solo for hare (H)

	S	H
S	4,4	0,3
H	3,0	2,2

Equilibrium Selection

Equilibrium selection: a game may have multiple equilibria, which can yield different expected returns to the agents.

- **Example:** Stag Hunt matrix game
- Two hunters choose: cooperate to hunt stag (S) or go solo for hare (H)
- Nash equilibria: reward-dominant (S,S) maximizes reward, risk-dominant (H,H) minimizes risk

	S	H
S	4,4	0,3
H	3,0	2,2

Equilibrium Selection

Equilibrium selection: a game may have multiple equilibria, which can yield different expected returns to the agents.

- **Example:** Stag Hunt matrix game
- Two hunters choose: cooperate to hunt stag (S) or go solo for hare (H)
- Nash equilibria: reward-dominant (S,S) maximizes reward, risk-dominant (H,H) minimizes risk
- (S,S) requires trust; (H,H) offers a safe, lower reward

	S	H
S	4,4	0,3
H	3,0	2,2

Equilibrium Selection

Equilibrium selection: a game may have multiple equilibria, which can yield different expected returns to the agents.

- **Example:** Stag Hunt matrix game
- Two hunters choose: cooperate to hunt stag (S) or go solo for hare (H)
- Nash equilibria: reward-dominant (S,S) maximizes reward, risk-dominant (H,H) minimizes risk
- (S,S) requires trust; (H,H) offers a safe, lower reward

	S	H
S	4,4	0,3
H	3,0	2,2

- Indep. Q-learning may bias towards (H,H) due to initial action uncertainty
- Early random actions can reinforce (H,H) since deviating from H is penalized if the other agent chooses H

Multi-Agent Credit Assignment

Multi-agent credit assignment: which agent's actions contributed to received rewards?

- At time step t all agents perform *collect*, each receiving reward $+1$
- Whose actions led to the reward?
- The agent on the left did not contribute
- For a learning agent that only observes s^t, a^t, r^t, s^{t+1} , disentangling the action contributions is difficult

Joint Actions for Addressing Multi-Agent Credit Assignment

Joint actions can help disentangle agent contributions. Consider the RPS game:

	R	P	S
R	0,0	-1,1	1,-1
P	1,-1	0,0	-1,1
S	-1,1	1,-1	0,0

Joint Actions for Addressing Multi-Agent Credit Assignment

Joint actions can help disentangle agent contributions. Consider the RPS game:

	R	P	S
R	0,0	-1,1	1,-1
P	1,-1	0,0	-1,1
S	-1,1	1,-1	0,0

1. Agents choose actions $(a_1, a_2) = (R, S) \Rightarrow$ agent 1 receives reward +1

Joint Actions for Addressing Multi-Agent Credit Assignment

Joint actions can help disentangle agent contributions. Consider the RPS game:

	R	P	S
R	0,0	-1,1	1,-1
P	1,-1	0,0	-1,1
S	-1,1	1,-1	0,0

1. Agents choose actions $(a_1, a_2) = (R, S) \Rightarrow$ agent 1 receives reward +1
2. Then agents choose $(a_1, a_2) = (R, P) \Rightarrow$ agent 1 receives reward -1

Joint Actions for Addressing Multi-Agent Credit Assignment

Joint actions can help disentangle agent contributions. Consider the RPS game:

	R	P	S
R	0,0	-1,1	1,-1
P	1,-1	0,0	-1,1
S	-1,1	1,-1	0,0

1. Agents choose actions $(a_1, a_2) = (R, S) \Rightarrow$ agent 1 receives reward +1
2. Then agents choose $(a_1, a_2) = (R, P) \Rightarrow$ agent 1 receives reward -1
3. Action value $Q(a_1)$ does not model agent 2, value for action R appears to be 0

Joint Actions for Addressing Multi-Agent Credit Assignment

Joint actions can help disentangle agent contributions. Consider the RPS game:

	R	P	S
R	0,0	-1,1	1,-1
P	1,-1	0,0	-1,1
S	-1,1	1,-1	0,0

1. Agents choose actions $(a_1, a_2) = (R, S) \Rightarrow$ agent 1 receives reward +1
2. Then agents choose $(a_1, a_2) = (R, P) \Rightarrow$ agent 1 receives reward -1
3. Action value $Q(a_1)$ does not model agent 2, value for action R appears to be 0
4. **Joint action value model** $Q_1(a_1, a_2)$ can represent the effect of agent 2:
 $Q_1(R, S) = +1$ and $Q_1(R, P) = -1$

Problem

- **Joint action space** can grow **exponentially** with number of agents:

$$|A| = |A_1| \cdot \dots \cdot |A_n|$$

- If agents have associated features in s (e.g. agent position) then $|S|$ also increases exponentially
⇒ How to scale efficiently to many agents?

Scaling to Many Agents

Changing number of agents from 3 to 5 increases the number of joint actions from 216 to 7776!

We covered:

- MARL learning process
- Independent and central learning
- Modes of operation in MARL
- Challenges of MARL

Next we'll cover:

- Foundational algorithms in MARL
