Lecture Outline

Part 1: Introduction

- Multi-agent systems
- Advantages of MARL vs SARL in multi-agent systems
- Challenges of MARL

Part 2: Reinforcement Learning Basics

- Markov decision processes
- Discounted returns
- Dynamic programming and temporal-difference learning

Part 1: Introduction

What is MARL?

Multi-agent reinforcement learning (MARL) is about finding optimal decision policies for two or more artificial agents interacting in a common environment.

- Applying reinforcement learning (RL) algorithms to multi-agent systems
- Goal is to learn optimal policies for two or more agents

MARL Applications

Competitive games

Multi-robot warehouses

Autonomous driving

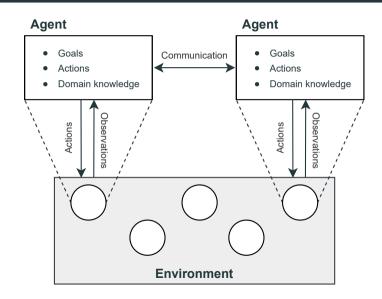

Automated trading

Mutli-Agent Systems

A multi-agent system consists of:

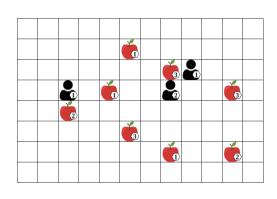

- Environment: The environment is a physical or virtual world whose state evolves and is influenced by the agents' actions within the environment.
- Agents: An agent is an entity which receives information about the state of the environment and can choose actions to influence the state.
 - ⇒ Agents are goal-directed, e.g. maximizing returns

Multi-Agent Systems

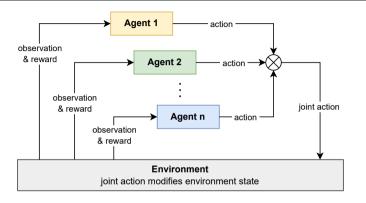

Example: Level-Based Foraging

- Three agents with varying skill levels
- Goal: to collect all apples
- Items can be collected if a group of one or more agents are located next to the item and the sum of agents' levels is greater than or equal to the item level
- Action spaceA = {up, down, left, right, collect, noop}

MARL for Solving Multi-Agent Systems

- Goal: learn optimal policies for a set of agents in a multi-agent system
- Each agent chooses an action based on its policy ⇒ joint action
- Environment transitions into new state; agents receive rewards + new observations

Why MARL?

Why should we use MARL to find optimal solutions to multi-agent systems rather than controlling multiple 'agents' using a single-agent RL (SARL) algorithm?

Why MARL?

Why should we use MARL to find optimal solutions to multi-agent systems rather than controlling multiple 'agents' using a single-agent RL (SARL) algorithm?

Decomposing a larger problem

- For example, controlling 3 agents each with 6 actions (see LBF example), the action space becomes 6³ = 216.
- Using MARL, we decompose this into three more tractable problems.

Why MARL?

Why should we use MARL to find optimal solutions to multi-agent systems rather than controlling multiple 'agents' using a single-agent RL (SARL) algorithm?

Decomposing a larger problem

- For example, controlling 3 agents each with 6 actions (see LBF example), the action space becomes 6³ = 216.
- Using MARL, we decompose this into three more tractable problems.

Decentralized decision making

- There are many real-world scenarios where it is beneficial for each agent to make decisions independently.
- E.g. autonomous driving is impractical for frequent long-distance data exchanges between a central agent and the vehicle.

New **challenges** arise in MARL:

• Non-stationarity caused by multiple learning agents

New **challenges** arise in MARL:

- Non-stationarity caused by multiple learning agents
- Optimality of policies and equilibrium selection

New **challenges** arise in MARL:

- Non-stationarity caused by multiple learning agents
- Optimality of policies and equilibrium selection
- Multi-agent credit assignment

New **challenges** arise in MARL:

- Non-stationarity caused by multiple learning agents
- Optimality of policies and equilibrium selection
- Multi-agent credit assignment
- Scaling in number of agents

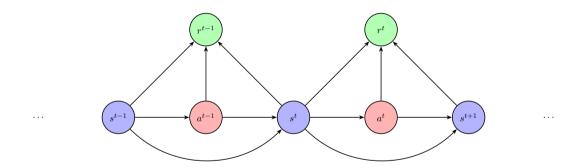

Part 2: Reinforcement Learning Basics

Back to RL Basics

RL Problem = Decision Process Model
e.g. MDP, POMDP,
multi-armed bandit + Learning Objective
e.g. discounted return with
specific discount factor

- RL algorithms learn solutions for sequential decision problems via repeated environment **interaction**
- Sequential decision process is defined formally as Markov decision process (MDP)
- Goal is to learn an optimal decision policy for a specific learning objective

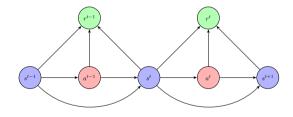

MDP As a Graph

MDP Definition

MDP is defined as a tuple $(S, A, \mathcal{R}, \mathcal{T}, \mu)$:

- S: Finite set of states with subset of terminal states \$\overline{S}\$ ⊂ S
- A: Finite set of actions
- \mathcal{R} : Reward function $\mathcal{R}: S \times A \times S \rightarrow \mathbb{R}$
- \mathcal{T} : State transition function $\mathcal{T}: S \times A \times S \rightarrow [0, 1]$
- μ : Initial state distribution $\mu: S \to [0,1]$ such that $\sum_{s \in S} \mu(s) = 1$ and $\forall s \in \hat{S}: \mu(s) = 0$

Markov property

- Future states are temporally independent of past states and actions, given the current state and action.
- $Pr(s^{t+1}, r^t | s^t, a^t, s^{t-1}, a^{t-1}, ..., s^0, a^0) = Pr(s^{t+1}, r^t | s^t, a^t)$

Markov property

- Future states are temporally independent of past states and actions, given the current state and action.
- $Pr(s^{t+1}, r^t | s^t, a^t, s^{t-1}, a^{t-1}, ..., s^0, a^0) = Pr(s^{t+1}, r^t | s^t, a^t)$

Full observability

- The agent can see the entire state of the environment.
- In practice, agent may only have partial view.

Markov property

- Future states are temporally independent of past states and actions, given the current state and action.
- $Pr(s^{t+1}, r^t | s^t, a^t, s^{t-1}, a^{t-1}, ..., s^0, a^0) = Pr(s^{t+1}, r^t | s^t, a^t)$

Full observability

- The agent can see the entire state of the environment.
- In practice, agent may only have partial view.

Stationarity

- The dynamics of the environment are assumed to be stationary.
- i.e. ${\mathcal T}$ and ${\mathcal R}$ remain constant through time.

Markov property

- Future states are temporally independent of past states and actions, given the current state and action.
- $Pr(s^{t+1}, r^t | s^t, a^t, s^{t-1}, a^{t-1}, ..., s^0, a^0) = Pr(s^{t+1}, r^t | s^t, a^t)$

Full observability

- The agent can see the entire state of the environment.
- In practice, agent may only have partial view.

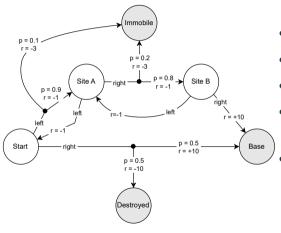

Stationarity

- The dynamics of the environment are assumed to be stationary.
- i.e. \mathcal{T} and \mathcal{R} remain constant through time.

Incomplete knowledge of MDP

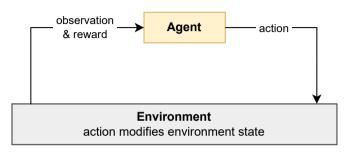

- The agent may only have knowledge of the action and state spaces (A, S)
- The transition and reward function $(\mathcal{T}, \mathcal{R})$ are usually to be **unknown**.

Mars Rover MDP Example

- Start is the initial state s⁰
- Two possible actions $A = \{right, left\}$
- Goal is to get to Base
- Rewards given by $\mathcal{R}(s, a, s')$ are shown as r.
- State transition probabilities given by $\mathcal{T}(s,a,s)$, are shown as p

RL for Optimizing Policies in MDPs

Value-Based RL

These methods indirectly update the policy by learning value functions.

Policy-Based RL

These methods update a parameterized policy function directly.

Expected Discounted Returns

Using RL, we aim to maximize the expected return.

- Returns (u) are the sum of rewards received over time
- If MDP is non-terminating (i.e. $t \to \infty$), we **discount** returns to ensures finite (discounted) returns

$$\mathbb{E}_{\pi}[u_t] = \mathbb{E}_{\pi}\left[\sum_{t=0}^{\infty} \gamma^t r^t\right]$$

- γ is the discount factor, such that $\gamma \in [0,1]$
- \bullet π is the behavior policy that determines which actions are chosen.

State-Value Functions

State-value functions $V^{\pi}(s)$ give the 'value' of state s when following the policy π .

$$V^{\pi}(s) = \mathbb{E}_{\pi} \left[u^{t} | s^{t} = s \right]$$

The return (u) can be recursively defined as:

$$u^{t} = r^{t} + \gamma (r^{t+1} + \gamma r^{t+2} + ...)$$

= $r^{t} + \gamma u^{t+1}$

Therefore:

$$V^{\pi}(s) = \mathbb{E}_{\pi} \left[r^{t} + \gamma u^{t+1} | s^{t} = s \right]$$

The Bellman Equation

$$V^{\pi}(s) = \mathbb{E}_{\pi} [r^{t} + \gamma u^{t+1} \mid s^{t} = s]$$

$$= \sum_{a \in A} \pi(a \mid s) \sum_{s' \in S} \mathcal{T}(s' \mid s, a) \left[\mathcal{R}(s, a, s') + \gamma \mathbb{E}_{\pi} [u^{t+1} \mid s^{t+1} = s'] \right]$$

$$= \sum_{a \in A} \pi(a \mid s) \sum_{s' \in S} \mathcal{T}(s' \mid s, a) \left[\mathcal{R}(s, a, s') + \gamma V^{\pi}(s') \right]$$

The last equation is known as the Bellman equation in honor of Richard Bellman.

The value of being in state s while following a fixed policy π is equivalent to the immediate reward (R(s, a, s') → r) received when taking action a in state s (π(a | s)) plus the discounted value of the next state s'.

State-Action Value Function

State-Action value functions $Q^{\pi}(s, a)$ are an extension on the State value functions. They condition the expected return on the current state and the action taken.

$$Q^{\pi}(s,a) = \mathbb{E}_{\pi} \left[u^{t} | s^{t} = s, a^{t} = a \right]$$

The state-action value Bellman equation is therefore:

$$Q^{\pi}(s,a) = \sum_{a \in A} \pi(a|s) \sum_{s' \in S} \mathcal{T}(s'|s,a) \left[\mathcal{R}(s,a,s') + \gamma Q^{\pi}(s') \right]$$

Greedy Policies

A policy can act *greedily* i.e. choosing actions which maximize the immediate reward and the value of the next state.

Greedy π using state value functions:

$$\pi(s) = \underset{a \in A}{\text{arg max}} \sum_{s',r} \mathcal{T}(s',r|s,a) \left[r + \gamma V(s') \right]$$

Or using the state-action value function:

$$\pi(s) = \underset{a \in A}{\operatorname{arg max}} Q(s, a)$$

Optimal Greedy Policy

A greedy policy with respect to a value function is optimal only when using the **optimal value function.**

An **optimal value function** for a MDP can be defined as:

$$V^*(s) = \max_{\pi'} V^{\pi'}(s), \quad \forall s \in S$$
$$Q^*(s, a) = \max_{\pi'} Q^{\pi'}(s, a), \quad \forall s \in S, a \in A$$

Therefore, the optimal policy is:

$$\pi^*(s) = \arg\max_{a \in A} Q^*(s, a)$$

Dynamic Programming

- Dynamic Programming (DP) is a family of algorithms to compute **optimal value functions** and **optimal policies in MDPs** (Bellman 1957; Howard 1960).
- In DP, we assume complete knowledge of the MDP, including the transition and reward function $(\mathcal{T}, \mathcal{R})$.
- Given complete knowledge, we can use the **Bellman equation** to find optimal value functions and policies.

Policy Iteration

Policy iteration is a DP algorithm that alternates between two steps:

- **Policy evaluation**: compute value function V^{π} for current policy π
- Policy improvement: improve current policy π with respect to V^{π}

$$\pi^0 \to V^{\pi^0} \to \pi^1 \to V^{\pi^1} \to \pi^2 \to \dots \to V^* \to \pi^*$$

Policy Iteration Pseudo Code

Algorithm Policy Iteration

```
1: Initialize \pi randomly, initialise V(s) arbitrarily for all s \in S except V(\text{terminal}) = 0
 2: repeat
         Policy Evaluation:
         repeat
 4:
             for each state s in S do
 5.
                 V(s) \leftarrow \sum_{s'} \mathcal{T}(s'|s, \pi(s)) [\mathcal{R}(s, \pi(s), s') + \gamma V(s')]
 6:
         until V(s) converges for all s \in S
         Policy Improvement:
         policy_stable ← true
10.
         for each state s in S do
             old action \leftarrow \pi(s)
11.
             \pi(s) \leftarrow \arg\max_{a} \sum_{s'} \mathcal{T}(s'|s,a) [\mathcal{R}(s,a,s') + \gamma V(s')]
12:
             if old_action \neq \pi(s) then
13.
14.
                 policy stable ← false
15: until policy stable return V, \pi
```

Value Iteration

Value Iteration uses the Bellman optimality equation

• Combines iterative policy evaluation and improvement into one single update equation.

Bellman Optimality Equation as update operator:

$$V^{k+1}(s) \leftarrow \max_{a \in A} \sum_{s' \in S} \mathcal{T}(s'|s, a) [\mathcal{R}(s, a, s') + \gamma V^k(s')], \quad \forall s \in S$$

- The max operator makes this the Bellman *optimality* equation.
- The equation expresses the value of a state as the maximum expected return achievable by taking the best action and then following the optimal policy.

Value Iteration Pseudo Code

Algorithm Value Iteration

- 1: Initialize: $V(s) = 0, \forall s \in S$
- 2: repeat
- 3: $\forall s \in S : V(s) \leftarrow \max_{a \in A} \sum_{s' \in S} \mathcal{T}(s'|s,a) \left[\mathcal{R}(s,a,s') + \gamma V(s') \right]$
- 4: **until** *V* converged **return** optimal policy π^* with:
- 5: $\forall s \in S$: $\arg \max_{a \in A} \sum_{s' \in S} \mathcal{T}(s'|s,a) \left[\mathcal{R}(s,a,s') + \gamma V(s') \right]$

Temporal-Difference Learning

Temporal-Difference (TD) learning is a family of RL algorithms that learn optimal policies and value functions based on data collected via environment **interactions**.

- These algorithms learn which actions yield the best returns by **trial and error** and exploring different actions and states
 - \Rightarrow Learns without **model** of environment's **reward** and **transition** functions $(\mathcal{R}, \mathcal{T})$
 - \Rightarrow Can learn **online**, updating the policy while interacting with the environment

Temporal Difference Update

The update for temporal-difference learning relies on value functions:

$$V(s^t) \leftarrow V(s^t) + \alpha \left[\mathcal{X} - V(s^t) \right]$$

or

$$Q(s^t, a^t) \leftarrow (s^t, a^t) + \alpha \left[\mathcal{X} - (s^t, a^t) \right]$$

- ullet X is the update target, serving as an estimate of the current state value.
- ullet α is the learning rate

Temporal-Difference Update

In SARSA (a basic TD algorithm), we use the experience tuple $(s^t, a^t, r^t, s^{t+1}, a^{t+1})$ to construct a target:

$$\mathcal{X} = r^t + \gamma Q(s^{t+1}, a^{t+1})$$

(The immediate reward plus the discounted value of the next state) - note the resemblance to the Bellman equation.

$$Q^{\pi}(s, a) = \sum_{a \in A} \pi(a \mid s) \sum_{s' \in S} \mathcal{T}(s' \mid s, a) \left[\mathcal{R}(s, a, s') + \gamma Q^{\pi}(s', a') \right]$$

The SARSA update rule thus becomes:

$$Q(s^{t}, a^{t}) \leftarrow Q(s^{t}, a^{t}) + \alpha[r^{t} + \gamma Q(s^{t+1}, a^{t+1}) - Q(s^{t}, a^{t})]$$

- Note the TD error $r^t + \gamma Q(s^{t+1}, a^{t+1}) Q(s^t, a^t)$.
- The TD update is bootstrapped
- Using the value **estimates** of the next state $(Q(s^{t+1}, a^{t+1}))$ to update the current state value $(Q(s^t, a^t))$

SARSA Pseudo Code

Algorithm SARSA

```
1: Initialize Q(s,a) = 0 for all s \in S, a \in A
2: for every episode do
        Observe initial state s<sup>0</sup>
        With probability \epsilon: choose random action a^0 \in A
4:
        Otherwise: choose action a^0 \in \arg \max_a Q(s^0, a)
5:
        for t = 0, 1, 2, ... do
6.
            Apply action a^t, observe reward r' and next state s^{t+1}
 7.
            With probability \epsilon: choose random action a^{t+1} \in A
8.
            Otherwise: choose action a^{t+1} \in \arg \max_{a} Q(s^{t+1}, a)
9.
             Q(s^t, a^t) \leftarrow Q(s^t, a^t) + \alpha[r^t + \gamma Q(s^{t+1}, a^{t+1}) - Q(s^t, a^t)]
10:
```

Convergence of SARSA

SARSA is guaranteed to converge to the optimal state-value function, for all $S \in S$ and $a \in A$, if:

• All state-action pairs are explored infinitely many times:

$$\forall s \in S, a \in A : \sum_{k=0}^{\infty} \mathbb{I}(s, a) \to \infty$$

• The learning rate α is reduced over time according to the "standard stochastic approximation conditions":

$$\forall s \in S, a \in A : \sum_{k=0}^{\infty} \alpha_k(s, a) \to \infty \quad \text{and} \quad \sum_{k=0}^{\infty} \alpha_k(s, a)^2 < \infty$$

ϵ -Greedy Policies

Using a greedy policy would violate the convergence condition of SARSA (infinite exploration of S and A).

- Intuitively, we must explore a wide range of states and actions to find state action combinations that yield high returns
- One solution is to add an **exploration** parameter $\epsilon \in [0,1]$. This gives us a stochastic **epsilon-greedy** policy.

$$\pi(a|s) = \begin{cases} 1 - \epsilon + \frac{\epsilon}{|A|} & \text{if } a \in \arg\max_{a'} Q(s, a') \\ \frac{\epsilon}{|A|} & \text{otherwise} \end{cases}$$

• With probability 1 $-\epsilon$, the policy chooses the greedy action, and with probability ϵ chooses an action uniformly at random.

34

Q-Learning

Q-learning (Watkins & Dayan 1992) is a popular TD algorithm which uses the Bellman optimality equation to update its value function estimates.

- By using the Bellman optimality equation, Q-learning directly learns the **optimal** state-action value function
- Q-learning is off-policy, meaning the policy followed to gather experiences is different from the optimized policy
- We use the ϵ -greedy policy to collect experiences

Q-Learning Update

The target in Q-learning uses the *max* operator to target the optimal Q-values directly.

$$\mathcal{X} = r^t + \gamma \max_{a' \in A} Q(s^{t+1}, a')$$

The Q-learning update is thus:

$$Q(\mathbf{s}^t, a^t) \leftarrow Q(\mathbf{s}^t, a^t) + \alpha \left[r^t + \gamma \max_{a' \in A} Q(\mathbf{s}^{t+1}, a') - Q(\mathbf{s}^t, a^t) \right]$$

Q-Learning Pseudo Code

Algorithm Q-Learning

```
1: Initialize Q(s, a) = 0 for all s \in S, a \in A

2: for every episode do

3: for t = 0, 1, 2, ... do

4: Observe current state s^t

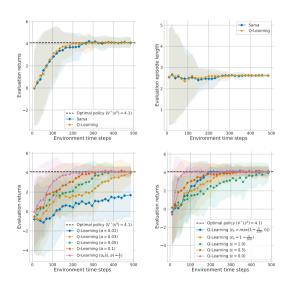

5: With probability \epsilon: choose random action a^t \in A

6: Otherwise: choose action a^t \in \arg\max_a Q(s^t, a)

7: Apply action a^t, observe reward r^t and next state s^{t+1}

8: Q(s^t, a^t) \leftarrow Q(s^t, a^t) + \alpha \left[r^t + \gamma \max_{a'} Q(s^{t+1}, a') - Q(s^t, a^t)\right]
```

Evaluating RL Algorithms

Y-axis:

- Average discounted evaluation returns.
 This shows us how our greedy policy would perform if we stopped learning at time step T.
- In some cases, undiscounted returns are easier to interpret and may be used instead.

X-axis:

- Cumulative training steps across episodes.
- Number of episodes can also be used. This might, however, distort the learning speed.

Summary

We covered:

- Multi-Agent Systems and the case for MARL
- MDPs
- Value Functions
- Dynamic Programming
- Temporal Difference Learning (SARSA and Q-Learning)

Next we'll cover:

• Games: Models of Multi-Agent Interaction
